Baltimore, MD 21203

Dear Mr. Mollenkopf:

Enclosed is the biological evaluation of hemlock woolly adelgid (HWA) at Raystown Lake. A total of twenty areas were surveyed. The majority of the surveyed stands have hemlock trees that are generally healthy, with some stands having light decline. Stands 1 and 10 have trees with moderate to severe decline. HWA population densities throughout the area are highly variable, ranging from none to heavy. HWA densities will continue to fluctuate in the coming years but impacts on hemlock health will continually worsen without intervention.

We recommend the following management option to protect important hemlock resources at Raystown Lake:

- Chemical treatment of high-valued infested hemlock trees in stands 2-4, 12-15, 17, 18, 20, 24, 25, and 30 using imidacloprid via. soil injection, soil drench or stem injection as appropriate. Treatment timing for these application methods is spring or fall.

Please contact Brad Onken (304-285-1546) if you have any questions concerning this report.

Sincerely,

JOHN W. HAZEL
Field Representative-MFO

March 2005

ABSTRACT

In the fall of 2004, USDA Forest Service personnel conducted surveys to evaluate hemlock woolly adelgid (HWA), *Adelges tsugae* population densities at Raystown Lake, and to assess the need for treatment. Current populations are sufficient to impact tree health in some of the areas surveyed, and the use of imidacloprid on high-valued infested hemlock trees in stands 2-4, 12-15, 17, 18, 20, 24, 25, and 30 is recommended.

INTRODUCTION

HEMLOCK WOOLLY ADELGID

Adelgids are small, soft-bodied insects that feed on plant sap. The family is divided into two genera: *Adelges* and *Pineus*. The members of this family feed exclusively on conifers. There are six species of *Adelges* that occur in North America, of which only one is native (Montgomery 1999), the Cooley spruce gall aphid (*Adelges cooleyi*). This adelgid occurs coast to coast in northern North America. Its primary hosts are recorded as white (*Picea glauca*), blue (*Picea pungens*), Sitka (*Picea sitchensis*), and Engelmann (*Picea engelmannii*) spruce (Baker 1972). It has an alternate host, Douglas fir (*Pseudotsuga menziesii*). There are 10 species of *Pineus* that occur in North America, of which seven are native. Four of these the pine bark adelgid (*Pineus strobi*); the pine leaf adelgid (*P. pinifoliae*); the red spruce adelgid (*P. floccus*); and the spruce gall adelgid (*P. similes*) seem to be indigenous to eastern North America (Drooz 1989, Montgomery 1999). These species attack eastern white pine (*Pinus strobus*), red spruce (*Picea rubens*), and black spruce (*Picea mariana*) but seldom cause extensive damage (Drooz 1989, Montgomery 1999). Little is known about the population dynamics, ecological role, or the predator and parasite complex associated with these native adelgids.

Native to Asia, the hemlock woolly adelgid (*Adelges tsugae*) is a pest of eastern hemlock (*Tsuga canadensis*) and Carolina hemlock (*T. carolina*) (Onken et al. 1999), both of which are considered highly susceptible to the adelgid, with no documented resistance (Bentz et al. 2002). The latter tree species is found only in the southern region of the Appalachian Mountains (Onken et al. 1999). The HWA is currently established in 16 Eastern States from Georgia to Maine, and tree decline and mortality have increased at an accelerated rate since the late 1980s. For example, in the Shenandoah National Park (SNP), hemlock crown health has declined since the early 1990s. In 1990, greater than 77 percent of the hemlocks sampled were in a "healthy" condition; by 1999, less than 10 percent were in a "healthy" condition (Akerson and Hunt 1998). In another study at SNP, tree mortality significantly increased from an initial 8 percent in 1990 to nearly 50 percent in 2000 (Bair 2002). In New Jersey less than 13 percent of stands surveyed in 1991 remain healthy. Twelve years after initial HWA infestations, tree mortality has reached more than 90% in some New Jersey hemlock stands (Mayer et al 2002).

The hemlock woolly adelgid is parthenogenetic (an all-female population with asexual reproduction) that has six stages of development: the egg, four nymphal instars, and the adult, and two generations a year on hemlock; each adult adelgid can produce 50 to 300 eggs in her lifetime (McClure 1989, 1995). The hemlock woolly adelgid also has a winged form that is produced by the spring generation. This form must complete part of its life cycle on spruce. The apparent lack of a suitable spruce host for this form in eastern North America results in a substantial loss of adelgids each year (McClure 1992b). Although natural mortality in HWA populations is commonly between 30 to 60 percent (McClure 1989, 1996), the reproduction potential of this insect remains high. Other mortality is

generally attributed to two likely causes: 1) an extended period of cold temperatures or rapid temperature changes that coincides with a susceptible period of development for the adelgid, and/or 2) a sufficient loss in the nutritional quality and quantity of the food source, which is associated with the decline in health and vigor of the host tree (McClure 1996, Onken et al. 1999). Adelgid feeding can kill a mature tree in about 5 to 7 years (McClure et al. 2001). This tiny insect (~ 1 mm) feeds on all life stages of hemlock, from seedling to mature, old growth tree. The first instar nymphs, called crawlers, search for suitable sites at the base of the hemlock needles, and insert their feeding stylets into the young hemlock twigs and are committed to that feeding site throughout the remainder of its development. The stylet bundle is more than three times the length of the insect and penetrates deep within the plant tissues. HWA does not deplete nutrients directly by feeding on the sap, but rather by depleting the food reserves from the tree's storage cells (McClure et al. 2001). Dispersal and movement of HWA during its egg and mobile first instar stages is associated with wind, birds, deer, and other forest dwelling mammals. Humans also move the adelgid during logging and recreational activities and movement of infested nursery stock (McClure 1995). Natural enemies capable of maintaining low-level HWA populations are nonexistent in eastern North America (Van Driesche et al. 1996, Wallace and Hain 1998).

HWA was first reported in the western U.S. in the 1920s (Annand 1924, McClure 2001). HWA populations on western tree species, including western hemlock (*Tsuga heterophylla*) and mountain hemlock (*T. mertensiana*), appear to be innocuous; these tree species are believed to be resistant because little damage has been reported (McClure 2001). Unfortunately, both these trees are of limited value for hybridization and planting due to their poor adaptation to the east coast environment (Bentz et al. 2002). In the East, HWA was first reported in 1951 near Richmond, Virginia. It was considered to be more of an urban landscape pest and was controlled using a variety of insecticides applied with ground spraying equipment. Observations of the adelgid were periodically reported in several Mid-Atlantic States in the 1960s and 1970s but it was not until the 1980s that HWA populations began to surge and spread northward to New England at an alarming rate. By the late 1980s to early 1990s, infestations of HWA were reported to be causing extensive hemlock decline and tree mortality in hemlock forests throughout the East (McClure 2001).

HEMLOCK IMPORTANCE

Eastern hemlock is an extremely shade tolerant tree species, capable of surviving for as long as 350 years underneath a shaded forest canopy (Quimby, 1996). It is a slow-growing long-lived tree. It may take 250-300 years to reach maturity and may live for 800 years or more (Godman and Lancaster 1990). Eastern hemlock forests create distinctive microclimates and provide important habitat for a variety of wildlife, such as birds, fish, invertebrates, amphibians, reptiles and mammals. In the Northeast, 96 bird and 47 mammal species are associated with hemlock forests at some point during their life (Yamasaki et al. 2000).

Hemlocks located along the shoreline of the lake are of aesthetic value and provide valuable wildlife habitat along the small streams and spring channels. Because of the limited hemlock habitat at Raystown Lake, resource managers have expressed a high priority to protect these trees.

HWA HISTORY AND OTHER STRESSORS AFFECTING HEMLOCK HEALTH CONDITIONS AT RAYSTOWN LAKE

HWA was first discovered at Raystown Lake in 1999 at the northern end of the lake. In 2002, a survey was conducted to determine the extent and magnitude of HWA infestations. Over 160 acres of hemlocks were surveyed and about 144 acres were determined to be infested with HWA.

The impacts of HWA and the droughts of recent years have stressed hemlock resources at Raystown Lake. So far, over 100 mature hemlock trees have succumbed.

In the fall of 2003, over 200 trees in stand 1 received trunk injections of a systemic insecticide imidacloprid (Pointer®), at 5 percent active ingredient to control HWA. In the spring of 2004, approximately 1,000 additional trees were treated in stands 1-4, 7, and 10 using the same treatment.

In the spring of 2004, 5,000 *Sasajiscymnus tsugae* (*S.t*) beetles were released in 2 locations (2,500/location) in Stand 6.

In the fall of 2004, chemical treatments for the control of HWA were applied using imidacloprid via trunk injections and soil injections (Merit®). Trunk injections were conducted on 1,119 trees in 15 stands (stands 2-5, 10, 12-16, 19, 20, 25, 27 and 28) and 43 trees received soil injections in stand 24.

Hemlocks exhibiting declining health conditions were also treated with an experimental micronutrient supplement at Raystown Lake. A total of 851 trees were treated with a soil injected micronutrient supplement in stands 1, 3, 4, 10, 12, 14, 15, 16, 17, 19, 20, 23, 25, 27 and 28. A total of 282 hemlocks in stands 1, 2, 5, 10, 13, 27 and 28 received a soil injected micronutrient supplement in combination with a Merit® treatment and a total of 25 acres of hemlocks trees in stand 1, 2 and 10 were aerially treated with a micronutrient supplement only.

METHODS

Live hemlock trees (> 6" dbh) were randomly selected for inspection within the survey areas. An assessment of tree vigor, branch tip dieback, crown position, dbh, and HWA population densities was conducted of each tree.

HWA infestation levels were designated as heavy, moderate, light or none based on the criteria listed below:

HWA – Based on the percentage of tips with adelgid present per 30 centimeters of hemlock twig length: Heavy (H) = (>50% infested)
Moderate (M) = (50% to 25% infested)
Light (L) = (<25% infested)
None (N) = (0% infested)

Vigor indicates the health of the tree crown based on the rating below:

Healthy (H) = tree appears to be in reasonably good health: less than 10% branch or twig mortality, discoloration, or dwarfed leaves present
Light Decline (LD) = branch mortality, twig dieback, foliage discoloration, or dwarfed leaves present on 10-25% of the crown

Moderate Decline (MD) = branch morality, twig dieback, foliage discoloration or dwarfed leaves on 26-50% of crown

Moderate-Severe Decline (MS) = branch morality, twig dieback, foliage discoloration or dwarfed leaves on 51-75% of crown

Severe Decline (SD) = more than 75% of the crown with branch mortality, dieback, discoloration or leaf dwarfing, but foliage still present indicating that the tree is alive

RESULTS

The survey areas are represented in Figure 1. The results of the survey are summarized in Table 1. Hemlock woolly adelgid infestations and tree health ratings are variable from stand to stand and even tree to tree throughout the survey area.

In stand 1, trees are generally in moderate health. Populations of HWA have generally collapsed as no adelgids were observed on the trees treated within the last 2 years or the non-treated trees.

In stands 2 and 12, trees are generally in light to moderate decline and HWA infestations ranged from none to heavy.

In stand 3, trees are generally healthy and HWA infestations are generally light to moderate.

In stands 4-6, 8, 9, 13, 17, 20, 24, 25, and 30, trees are generally healthy and HWA population densities are generally light to none.

In stands 11 and 18, trees are generally healthy to light decline and HWA population densities are generally light to moderate.

In stands 14 and 15, trees are generally healthy to light decline and HWA infestations are generally moderate.

No individual tree data was collected for stand 16. Trees in this area were very scattered and generally in severe decline.

In stand 10, trees are generally in moderate to severe decline and HWA population densities are light to none.

No data was collected for stands 19 and 22 because of limited accessibility.

DISCUSSION

Tree health and HWA population densities are highly variable within the hemlock stands surveyed at Raystown Lake. The majority of the stands have trees that are basically in good health and HWA infestations range from none to moderate. In stands 1 and 10 where tree health is in moderate to severe decline and HWA population densities range from none to moderate. The tree health in stands 2 and 12 is light to moderate and HWA population densities range from none to heavy. Stands 5, 6, 8, 9, and 11 had been identified as potential areas to establish predator beetles however current HWA densities in these stands are not sufficient for this purpose.

Management Considerations

Management options for preserving hemlock stands are limited by the biology and feeding behavior of HWA, pest population densities, site conditions (i.e. proximity to streams), and limited chemical and application technology currently available.

Chemical treatments: Aerial spray using horticultural oil or insecticidal soap is not an option because aerial sprays could not provide the needed "saturation" necessary to ensure that the insecticide adequately covers the insect. Aerial spraying with more toxic insecticides (e.g. malathion or diazinon) would have very significant, unacceptable impacts on a wide range of non-target insects and other animals and limited control benefits (Evans 2000). Application of insecticides using ground spraying equipment is limited to areas accessible to heavy hydraulic spray equipment and areas where over spray or run off would not contaminate streams, lakes or ponds.

Biological control: There are no known parasites of adelgids. The first predator beetle to be imported and released for biological control is a tiny, black lady beetle, *Sasajiscymnus tsugae* (*S.t.*), from Japan. So far, over a million *S.t.* beetles have been released in over 100 sites in 15 eastern states from Georgia to Maine. Several species of *Scymnus* lady beetles from China and a derodontid beetle *Laricobius nigrinus* from the Pacific Northwest are also approved for release. Establishment of the latter predators began in 2004. It is likely that a complex of natural enemies will be necessary to maintain HWA below damaging levels.

Establishment of predator beetles of HWA requires a viable and healthy population of adelgids, which ironically is associated with healthy hemlocks. These predators are not expected to have an immediate effect on HWA populations at the stand level but are expected to provide longer term control as part of a self perpetuating natural enemy complex. Release of predator beetles should not take place in close proximity of hemlock trees that have received chemical treatments because of the effect of the chemical insecticide on beetles should they feed on adelgids that ingest the insecticide. Preferred release sites are newly infested sites where trees and adelgids still healthy. All predator beetles are laboratory reared and the number of predators available in any given year is variable depending on the success of the rearing facilities to locate good quality host material for a food source. In 2005 we expect very limited quantities.

Considering the above limitations, foliar ground spraying using hydraulic sprayers is not feasible in any of the surveyed areas because of limited access and stream/lake-side locations. Stands 5, 6, 8, 9, and 11, designated by the Corps as potential areas for beetle releases do not currently support sufficient HWA populations and with the limited availability of beetles this coming year, beetles predators will not be available for release at Raystown Lake. Recommended management options are: 1) use backpack sprayers using horticultural oil on hemlock seedlings and saplings where protecting hemlock regeneration is important; and 2) the use of systemic insecticides, particularly the use of imidacloprid on infested mature hemlocks.

Systemic Insecticides

Several systemic insecticides are labeled for adelgids and can be injected (e.g. imidacloprid, bidrin or Metasystox-R[®]) or implanted (e.g. acephate) into hemlock trees, and another (Merit[®]) can be applied as

a soil drench or injected into the soil around hemlock trees. These insecticides are absorbed and translocated by the vascular system of the tree to feeding adelgids and will effectively suppress HWA populations (Doccoła et al. 2003, Webb et al. 2003, Evans 2000, Steward and Horner 1994, McClure 1992a). Soil injection in sandy or saturated soils should be avoided as leaching of the insecticide into the soil profile and groundwater (McAvoy et al. 2002) is a possibility. Soil injections immediately adjacent to creeks or other open waters should also be avoided. Imidacloprid formulated as a trunk injection is available under the trade names Pointer®, IMA-jet® and Imicide® are currently labeled for tree injection for the control of adelgids. However, only IMA-jet® and Imicide® are labeled for applications in the forest environment. Acephate controls adelgids and scale pests and is available as a trunk implant under the trade name ACECAP®.

Imidacloprid

Imidacloprid is a relatively new insecticide in the family of chemicals called neonicotinoids (Felsot 2001) in the chloronicotinyl subgroup (USDA Animal and Plant Health Inspection Service 2002). It has a mode of action similar to that of the botanical product nicotine, functioning as a fast-acting insect neurotoxicant (Schroeder and Flattum 1984) that binds to the nicotinic receptor sites in the postsynaptic membrane of the insect nerve (USDA Animal and Plant Health Inspection Service 2002), mimicking the action of acetylcholine, and thereby heightening, then blocking, the firing of the postsynaptic receptors with increasing doses (Schroeder and Flattum 1984, Felsot 2001). Because imidacloprid is slowly degraded in the insect, it causes substantial disorder within the nervous system, leading in most cases to death (Mullins 1993, Smith and Krischik 1999).

Imidacloprid is considered to have low to moderate mammalian toxicity (Mullins 1993), largely because it does not bind nerve receptors in mammals sufficiently to trigger nervous activity (Felsot 2001). The selective toxicity of imidacloprid is perhaps best illustrated by its use in flea treatments approved for cats and dogs. Advantage® is applied directly to the animal's skin; this preparation carries very little, if any, risk to the animal or to the people, including children, who may handle the animal (USDA Animal and Plant Health Inspection Service 2002). Chronic (repeated dose) toxicity studies have demonstrated that imidacloprid is not carcinogenic and is not mutagenic and demonstrates no primary reproductive toxicity (Mullins 1993). In studies of metabolic fate in rats, imidacloprid was rapidly absorbed and eliminated in the excreta (90 percent of the dose within 24 hours) with little bioaccumulation (0.5 percent of the dose after 48 hours) and no biologically significant differences occurring between sexes, dose level, and route of administration (USDA Animal and Plant Health Inspection Service 2002). Imidacloprid is an insecticide exhibiting both systemic and contact activity. The spectrum of activity primarily includes sucking insects (aphids, whiteflies, leaf and plant hoppers, thrips, plant bugs, and scales), many Coleopteran species, and selected species of Diptera and Lepidoptera. Activity has also been demonstrated for ants (Hymenoptera); termites (Isoptera); and cockroaches, grasshoppers, and crickets (Orthoptera). No activity has been demonstrated against nematodes or spider mites (Mullins 1993). In spider mites, imidacloprid has been demonstrated to cause an egg-laying enhancement (James and Price 2002). Since spider mites can be a problem in ornamental hemlocks, imidacloprid-treated trees should be carefully monitored for increases in mite populations.

Little is known about the biotransformation and bioactivity of the metabolites of imidacloprid in hemlock. What is known is that trunk-injected imidacloprid generally requires a week or longer to provide adelgid control, with protection lasting for up to 2 years (Tater et al. 1998, Silcox 2002). The soil injection or soil drench methods of imidacloprid treatments take several months for translocation to occur but provides better consistency in treatment efficacy when compared to stem injections.

RECOMMENDATIONS

The use of imidacloprid based insecticides is recommended for use on high-valued infested hemlock trees in stands 2-4, 12-15, 17, 18, 20, 24, 25, and 30. Where possible, soil injections are preferred over stem injections as treatment efficacy has been shown to be more consistent. Merit[®] applied at 1 ounce per 30 cumulative inches of trunk diameter (dbh) is recommended for the soil injections, and treatment timing should be in the spring or fall. The insecticide recommended for the stem injections is IMA-jet[®] at 5% active ingredient with the number of application sites determined by dbh. Criteria for number of application sites is as follows: 4 application sites for 6-16 inches dbh, then add one additional application site for each additional 4 inches of dbh. Hemlocks tend to have faster uptake of the stem injected insecticide in the fall months.

With treatment options comes the potential for non-target effects; land managers must balance the risk of these effects with the potential benefits that come with the control of the HWA. As a best management practice, we are recommending that hemlocks within 50 feet of open water be treated with a stem injection rather than a soil treatment. Ground spraying using horticultural oil to protect hemlock seedlings and saplings by means of a backpack sprayer should be considered in areas where protecting younger hemlocks is desirable. A 2% solution of horticultural oil applied in early summer or early fall is recommended as adelgids have not yet developed the wool covering that can impede penetration of the insecticide.

Resource managers should annually monitor tree health and adelgid conditions, as any treatment intervention action undertaken will require a vigilant monitoring and treatment program until sufficient biological control agents are established.

Stand 16 – No data collected – few trees and in severe decline

Stand 19 – No data collected – unreachable branches

Stand 22 – No data collected – stand inaccessible

*Tree has received chemical stem injection within the last 2 years

¹-DBH= estimated tree diameter at breast height to nearest inch

²-Crown position: D=dominate, CD=codominant, I=intermediate, S=suppressed, OG=open grown

³-Percentage of tips with adelgid present per 30 centimeters (cm) of hemlock twig length: Heavy = (>50% infested), Moderate = (50% to 25% infested), Light = (<25% infested), None = (0% infested)

⁴-Scale presence based on visual estimates from 30 cm length of hemlock branch: HEAVY = (>1/needle on average), MODERATE = (1/needle on average), LIGHT = (<1/needle on average), NONE = (0% infested)

⁵-Percentage of dead tips per 30 centimeters of hemlock twig length

⁶- Vigor = Tree crown health:

Healthy (H) = tree appears to be in reasonably good health: less than 10% branch or twig mortality, discoloration, or dwarfed leaves present

Light Decline (LD) = branch mortality, twig dieback, foliage discoloration, or dwarfed leaves present on 10-25% of the crown

Moderate Decline (MD) = branch mortality, twig dieback, foliage discoloration or dwarfed leaves on 26-50% of crown

Moderate-Severe Decline (MS) = branch mortality, twig dieback, foliage discoloration or dwarfed leaves on 51-75% of crown

Severe Decline (SD) = more than 75% of the crown with branch mortality, dieback, discoloration or leaf dwarfing, but foliage still present indicating that the tree is alive
